Abstract. The performance of treated kaolinite obtained from three types treatment that was calcination at 600 °C (K600), 800 °C (K800) and acid treated of K800 (KA800). All catalysts were tested for their catalytic activity via electrolysis process through (trans)esterification of soy bean oil at room temperature. X-ray diffraction (XRD) and Fourier transform infrared (FTIR) was performed to characterize the microstructures and chemical properties of as-prepared treated kaolinite material. The effect of catalyst amount (2, 3 and 5 wt.%) was evaluated for the conversion of FAME from soybean oil and followed by GC-MS, determining of the purity of FAME at different operation variables. The result showed that for KA800 as catalyst, the FAME conversion was the highest as well as 18,85% at 3 wt.% catalyst of catalyst loading in the mixture, respectively.

1 Introduction

The depletion of fossil fuel production be accompanied with climate change in the world has encourage world researchers to find renewable energy sources namely biodiesel as an alternative energy source developed to substitute the fossil fuels. Based on data between 2005 and 2015 presented by Naylor and Higgins (2017) showed that the global biodiesel production continues to increase by ~ 23% per year despite a sharp decline in crude oil prices. This coincides with a sharp rise in the price of crude oil and diesel fuel that makes some countries support the use of biodiesel [1].

Biodiesel synthesis processes typically use renewable sources such as vegetable oils, animal fats and recycled cooking oil [2] are carried out by (trans)esterification of triacylglyceride with methanol and assisted with homogeneous alkaline catalysts, such as NaOH and KOH which produce Methyl Ester Fatty Acid (FAME) as a product main and glycerol as by-products [3]. Homogeneous alkaline catalysts are extremely sensitive to Free Fatty Acid (FFA) contained in low quality cooking oils that lead to saponification, decreased catalyst quality, decreased synthesis efficiency and increased production costs. Guan and Kusakabe [4] reported that the synthesis of biodiesel from used-cooking oil using electrolysis process have a yield percentage of > 97%. This process runs quickly at relatively low temperatures, but this method is less efficient because once the process is complete, it has to separate between the biodiesel and the homogeneous catalyst that used. In addition, the homogeneous catalyst could not be regenerated after (trans)esterification process. Furthermore, a large amount of Indonesian society on the consumption of palm oil as a

vegetable oils thus increasing the availability of used-cooking oil as feed-stock in the producing of biodiesel. The conversion of used-cooking oil into biodiesel is a smart move, which gives three advantages at once namely (i) its economic value, (ii) becomes a solution for handling used-cooking oil and (iii) producing an environmentally friendly biodiesel products [3].

Jorge et al. (2011) [5] has reported the production of biodiesel from used-cooking oil by transesterification reaction using methanol and kaolinite as a solid acid catalyst. This study has become a positive alternative to utilizing used-cooking oil as feed-stock combined with a cheap kaolinite catalyst. Kaolinite is a raw material that has a selling value, cheap, available, non-corrosive and environmentally friendly materials. In this study, the enhancement of FAME synthesis from soybean oil using electrolysis process by treated kaolinite thermal and acid as catalyst in room temperature was demonstrated.

2 Methodology

2.1 Chemical and equipment

Soybean oil was obtained from supermarket. High grade of methanol, HCl, NaCl and co-solvent THF were purchased from Merck, Germany and the kaolinite was purchased from Wako Chemical, Japan. Fig. 1 shows an electro-catalytic cell (70 ml) contains two graphite electrodes (Ø 0.8 mm x 130 mm) that were separated by a distance of 15 mm [3-4]. The qualities of soybean oil were determined by physicochemical analysis and the results were shown in the Tab. 1.

2.2 Preparation and characterization of catalyst

Treated kaolinite was prepared by calcination of a natural kaolinite at 600 °C and 800 °C. This kaolinite, more reactive than the parent kaolinite, was submitted to acid activations. Acid activation was carried out with 6 M HCl at room temperature with times of treatment of 24 h [6]. X-ray diffraction (XRD), Fourier transform infrared (FTIR) was performed to characterize the microstructures and chemical properties of as-prepared acid-calcination of kaolinite material. The performance of FAME synthesis using electrolysis was compared between acid activation and treated kaolinite thermal. The FAME phase was separated from glycerol and then washed with deionized water to remove the residual inorganic components. Concentration of produced FAME and unreacted oils remaining in the product were measured using GC-MS.

2.3 Catalytic testing

Soybean oil was used as a feedstock to obtain optimal condition before implemented to used-cooking oil for FAME synthesis. Effect of catalyst amount (2, 3 and 5 wt.%) were evaluated for the conversion of FAME from soybean oil. The reaction mixture was agitated using magnetic stirrer. The electrolytic cell was filled with 70 ml of reaction mixture containing soybean oil, methanol, THF as a co-solvent. The methanol-to-oil molar ratio was 6:1 and co-solvent-to-methanol molar ratio was 1:1 were added on the basis of oil weight of the entire reaction mixture, respectively. The electro-catalytic was carried out at room temperature (25 °C) using a constant voltage of 18.2 V for 60 mins [3-4]. Fig. 2 shows a step of optimization process for biodiesel production in this study. This method is free from hazardous and expensive reagents, contamination and the product can be separated by simple filtration.

3 Results and discussion

3.1 Catalyst characterization

Generally, the structural of clay material changed after the thermal and acid treatment. Figure 3 shows the XRD profiles of the untreated and treated kaolin samples. The parent clay shows well-defined reflections at 2θ value of 12° , 25° (corresponding to the d values of 7.154 Å). These peaks correspond to the reflections from [001], which are typical characteristic peaks of kaolinite [7]. After acid treatment, the peak intensity of the clay was found to decrease, since leaching was quite severe with strong acids. This was attributed to the structural disorder that occurred owing to the acid leaching, which affects the crystalline character of the clay. The increase in intensity and/or narrowing of the peak may be related to the increase of crystallite size and/or the decrease of the mean lattice strain [8].

The FTIR spectrum of the clay peaks at 3673, 1119, 1044, 946, and 798 cm^{-1} [6] as shown in Fig. 4. There was not much variation in the peak pattern for acid treated kaolinite. However for thermal treated kaolinite, the peak intensity was found to decrease progressively indicating the loss of structural water with a reorganization of the structure; only a small part of AlO_6 octahedra is maintained, while the rest are transformed into much more reactive tetra- and pentacoordinated units [6].

3.2 Effect of treated kaolinite on the FAME synthesis

Table 2 shows the FAME conversion from soybean oil using treated kaolinite as catalyst in the electrolysis process. Generally, kaolinite which had been calcinated at 600 and 800 °C give better result in electrolysis process responded high FAME yield compared with acid kaolinite, and it was affected by 3% of catalyst loading. In K800 catalyst, all of the OH band disappears due to dehydroxylation via by calcination, thereby producing thermally activated kaolinite. These transformation occurs with the loss of structural water (see Fig. 4) in the kaolinite framework. The rest of the kaolinite was transformed into much more reactive tetra and pentacoordinated units [6]. Thus, a mild and efficient method has been developed for the (trans)esterification of fatty acid to their corresponding fatty acid methyl ester by using activated kaolinite clay in good yield. This method

is free from hazardous and expensive reagents, contamination and the product can be separated by simple filtration.

It was showed that excellent conversion rates (as high as 18.85%) were obtained in 3 wt.% of acid kaolinite (KA800) as a catalyst loading since total FAME yield was the highest (see Fig. 3). Total FAME on the K800 catalyst was as much as 6.47% in 3% catalyst loading, while on the K600 catalyst was as much as 2.2% in 5% catalyst loading. This fact shows that acid kaolinite was a high reactive catalyst in the (trans)esterification reaction. While, thermal kaolinite (i.e K600 and K800) showed low active catalyst, resulting a low FAME conversion (1.63% for K800 and 0% for K600).

Figs. 5 show the FAME profiles from biodiesel using kaolinite thermal and kaolinite acid as catalyst in the electrolysis process. There is no sharp different of FAME yield when using thermal (K800) and acid kaolinite (KA800) at 800 °C as catalyst. However, a sharp different FAME conversion showed when using thermal kaolinite at 600 °C. High to low FAME conversion (%) from used-cooking oil was as follow methyl linolein > methyl dhypalmitine > methyl hexadecanoate using kaolinite acid, respectively. These results were different for each catalyst used in the electrolysis process. Therefore, the amount of methyl ester produced was not affected by a certain methyl ester type.

Table 2. FAME conversion from soybean oil using treated kaolinite as catalyst

Treated kaolinite	Catalyst loading (%)	FAME yield (g) ^b	Purity (%) ^c	Yield (%) ^d
Without catalyst ^a	0	2.12	42.17	3.58
Thermal (800 °C), K800	2	32.93	5.76	3.79
	3	27.53	11.75	6.47
	5	22.62	3.61	1.63
Acid (800 °C), KA800	2	26.57	9.77	5.19
	3	19.44	48.47	18.85
	5	25.57	9.35	4.78
Thermal (600 °C), K600	2	-	-	-
	3	31.38	1.57	0.99
	5	30.74	3.58	2.20

^a The calculation was based on 25 g soybean oil as feed-stock, ^b FAME yield after washing and solvent evaporation, ^c percentage area (%) from GC-MC, ^d Yield (%) = [FAME yield (g)/Oil mass (g)] × Purity (%).

Fig. 5 FAME conversion from soybean oil in the electrolysis process using kaolinite thermal 800 °C (K800) (a), kaolinite acid 800 °C (KA800) (b) and kaolinite 600 °C (K600) as a catalyst.

4 Conclusions

The enhancement of FAME yield from the (trans)esterification of used-cooking oil using electrolysis process with acid kaolinite (KA800) as a catalyst had been evaluated. Acid kaolinite (KA800) as a catalyst could be a better material to enhance the electrolysis process. High catalyst concentration (3 wt. %) of KA800 with 60 minutes of electrolysis time at room temperature was required in order to get a high FAME yield as much as 18.85 % compared with thermal kaolinite K600 and K800 as a catalyst. In contrast, the results were not significantly on the FAME yield without catalyst in the electrolysis process.
