Abstract. This paper is devoted to study the feasibility of combining photocatalytic degradation with membrane filtration for the removal of organic pollutants. As a result, we have successfully prepared low-cost microfiltration membranes based on clay and phosphate. It is expected that the phosphate and clay composite membrane can have multifunctional separation and photocatalysis simultaneously and this type of composite membrane can play an important role in the photocatalytic reaction in presence of TiO₂ and the separation process. We then tested the efficiency of the direct coupling of photodegradation and filtration to determine the rate of release of TiO₂ particles through the microfiltration membrane. However, we have seen that the recovery of TiO₂ exceeds a 96%, as well as the removal of products from the photodecomposition of the reaction mixture in the membrane photocatalytic reactor. In our case the methylene blue elimination rate exceeds 75%.

1 Introduction

Nowadays water pollution, caused by hazardous organic chemicals used in industry and agriculture, is a very serious problem. Food, pharmaceutical, pesticides, the textile dyeing and finishing industry produces large volumes of discharge effluent and is considered as one of the major industrial pollutants.

Compared with conventional water treatments, which operate in discontinuous and produce large quantities of sludge which are disposed in land fill, the membrane processes are used to purify water continuously, without chemical additives. Therefore microfiltration (MF) separation is widely used as a solid-liquid separation technique in the drink and food industries and in biotechnology.

The microfiltration membrane we made from natural Moroccan clay [1-3] and phosphate [4] show their potentialities in the rationalization of productions systems. Their intrinsic characteristics of efficiency, operational simplicity and flexibility, relatively high selectivity and permeability for the transport of specific components, low energy requirements, good stability under a wide spectrum of operating conditions, easy control and scale up have been confirmed in a large variety of application, and operations.

Till now, heterogeneous photocatalysis has been mainly applied for environmental remediation because the photogenerated active species are capable to mineralize efficiently almost every organic pollutant. In general, photocatalysis can be defined as an acceleration of a photoinduced reaction by the presence of a photocatalyst [5]. Also that, Photocatalysis is one of the so-called "Advanced Oxidation Processes" (AOPs). AOPs are based on the generation of very reactive species—hydroxyl radicals (OH•) that could oxidize wide spectra of organic matter in water quickly and non-selectively [6]. Although, the presence of these compounds in the environment corresponds to low concentration levels, its continuous input from wastewater treatment plants or direct discharge to natural riverbeds may represent a long-term potential threat for the aquatic and terrestrial ecosystems. A coupling system of membrane separation and photocatalytic oxidation has been evaluated for the removal of organic pollutants in wastewaters [7].

Coupling photocatalysis and membrane separation can be use three main configurations can be distinguished: (a) irradiation of the feed tank, (b) irradiation of the membrane module or (c) irradiation of an additional reservoir (photoreactor) which is located between the feed tank and the membrane module Figs 1-3 [6]. In some cases the light source can be positioned above

* Corresponding author: n.elbaraka@uiz.ac.ma

both, membrane module and feed tank (or inside them, when the immersed UV lamps are used).

Fig. 1. Hybrid photocatalysis-membrane processes utilizing irradiation of the additional reservoir located between the feed tank and membrane module.

Fig. 2. Hybrid photocatalysis-membrane processes utilizing irradiation of the membrane module.

Fig. 3. Hybrid photocatalysis-membrane processes utilizing irradiation of the feed tank.

The aim of this work is to understand this behavior and to improve the performance of coupling photocatalysis and membrane separation, in order to take advantage of the benefits of both the photocatalytic and membrane technology for water treatment. The aqueous solution containing methylene blue is fed to the membrane unit, obtaining a permeate free of pollutants and a rejected flux with high concentration. Subsequently, the rejected stream was treated by photocatalytic system of them using TiO_2 as heterogeneous catalyst.

A comparative study between the photocatalytic coupling-clay microfiltration membrane and the photocatalytic coupling-phosphate microfiltration membrane for the removal of methylene blue using the configuration shown in Fig.3.

2 The use of methylene blue (MB) in photocatalytic-membrane coupling

Most of industries like textiles, paper, plastics, leather, food, and cosmetics industries use dyes or pigments to color their product. It can cause eye burns causing permanent injury to human and animal eyes. Inhalation may cause respiration difficulties and oral ingestion may cause burning, nausea, vomiting, sweating and heavy cold sweats [8]. The treatment of industrial discharges containing this type of dye is of great interest [9-10]. Indeed, the validation study of this new method will be based on this dye (MB) which is a cationic dye with broad applications such as dye for paper, hair, and cotton and filters for medical surgery [11]. This pollutant not only deteriorates water quality but also significantly affects the environment and human health [12], this is why this dye is chosen as a representative model of medium-sized organic pollutants.

The aim of this work is to understand this behavior and to improve the performance of coupling photocatalysis and membrane separation, in order to take advantage of the benefits of both the photocatalytic and membrane technology for water treatment. The aqueous solution containing methylene blue is fed to the membrane unit, obtaining a permeate free of pollutants and a rejected flux with high concentration. Subsequently, the rejected stream was treated by photocatalytic system of them using TiO_2 as heterogeneous catalyst.

3 Materials and methods

3.1 Materials

Methylene blue is a cationic dye of index C. I 52015, formula $\text{C}_{16}\text{H}_{18}\text{N}_3\text{SCl}$ and its molar mass is 319.85 g. mol⁻¹. Its visible spectrum is shown in Figure 4 [13].

Fig. 4. Visible spectrum of the methylene blue dye studied.

The semi-developed formula of this dye is shown in Fig.5.

Fig. 5. Molecular Structures of Methylene Blue.

The raw clay used in this work is clay taken from a natural basin in the region of Souss (Morocco), crushed and sieved to obtain fractions $\leq 125 \mu\text{m}$ and then dried at 100°C for 24 h.

Natural Moroccan phosphates from Khouribga was used to prepare lixiviated phosphate, the powder was crushed and sieved to obtain fractions $\leq 125 \mu\text{m}$ with disc mills Mc call [4].

Chemical analyses of raw Moroccan clay and phosphate were carried out using the X-ray fluorescence spectrometer, the results are grouped in Table 1.

Table 1 : Mineralogical composition of clay and phosphate.

Element	Clay sample	Phosphate sample
	Weight %	Weight %
Al_2O_3	43	0.29
SiO_2	35	1.4
Fe_2O_3	15	0.12
Na_2O	3.5	1.1
CaO	1.5	51.59
K_2O	1.2	0.06
MnO	0.03	-
P_2O_5	-	33.4
SO_3	-	1.56
CO_2	-	4.39
MgO	-	0.25
F-	-	4.08

Anatase-type titania have been proven as environmental friendly catalysts because of its capability to decompose the different organic and inorganic pollutants [14]. However, the best photocatalytic performances with maximum quantum yields have been always obtained with titania [15]. In addition, anatase is the most active allotropic form of TiO_2 among the various ones available [16]. Unfortunately, due to a wide band gap (about 3.2 eV) TiO_2 is inactive under visible light [17]. Recently, numerous investigations have been focused on different modifications of TiO_2 in order to improve its activity under UV irradiation or to reduce the band gap energy so that it is able to utilize the visible light [18–20]. An overview of various modification techniques which could improve TiO_2 activity under visible light was recently presented by Rehman et al. [17].

3.2 Methods

3.2.1 Water permeability test

Before using the elaborated ceramic membranes, it is necessary to make a test to determine the permeability to distilled water. The agitated reactor is pre-filled with distilled water, then a valve was used to control the pressure in the system, it varies between 0 and 2 bar, the valve is opened which makes it possible to send the water with the aid of a pump to the microfiltration reactor Fig.6. Membranes were conditioned by immersion in pure deionised water for a minimum of 24 h before the filtration tests.

Fig. 6. Scheme of the pilot of filtration.

3.2.2 Methylene blue filtration on ZrO_2 / phosphate and ZrO_2 / clay

We performed a BM filtration at an initial concentration of 25 ppm on a tubular membrane of ZrO_2 deposited on a phosphate support [4], the experiment was done in absence of TiO_2 and at a pressure of 1 bar. We have thus realized the same study and the same condition, but this time on a tubular clay microfiltration membrane.

Next, we carried out a filtration in the presence of TiO_2 through the membrane of ZrO_2 /Phosphate under the same conditions of BM concentration and pressure and without irradiation.

3.2.3 Study of BM adsorption on TiO_2 in darkness

The adsorption of dyes on the surface of semi-conductors is an important process. Indeed, the adsorption of the micro pollutant on the photocatalyst is a step prior to its degradation, very important for the development of the photodegradation reaction. It should be noted, however, that this process is debated. According to some authors [7-9], adsorption is a prerequisite for photodegradation.

The adsorption capacity of the methylene blue dye per unit mass of TiO_2 has been calculated using the following formula:

$$q = [(C_0 - C_t) \times V] / m_{\text{TiO}_2} \quad (1)$$

Where q is the quantity of BM adsorbed at time t, m the mass of TiO_2 (mg/g TiO_2), C_0 the initial concentration of BM (mg.L^{-1}) and C_t the concentration of BM at time t

a. . Determination of adsorption equilibrium time

All adsorption isotherms were performed in the dark after a 60 min equilibrium period at natural pH and 25°C. The same amount of TiO₂ adsorbent (1 g.L⁻¹) Various aqueous dye solutions were added to 100 mL at concentrations 20, 40, 60, 80 and 100 mg.L⁻¹ before being mechanically agitated at 200 rpm at room temperature.

b. Effect of temperature

The influence of temperature was studied using a thermostat bath to maintain temperature at desired value (25°, 30°, 35°, and 40°C). The experiments were achieved by adding 12 mg/L of methylene blue solution.

c. Effect of pH

The influence of the pH of the solution on adsorption was studied using different pH values. The experiments were carried out by adding 0.2 g/L of TiO₂ to the Methylene blue (T=25°C, C₀=10 ppm).

d. Effect of TiO₂ doses

The study of the effect of increasing the quantity of semiconductor on the adsorption of dyes, for the BM dye, within a series of concentrations of the catalyst (TiO₂) stretching from 0.5 g/L to 3 g/L and a dye concentration of 20 ppm.

3.2.4 Removal of MB from the membrane-photocatalytic reactor

After testing the reactor for distilled water and testing the adsorption of MB under different conditions, we performed photocatalytic degradation experiments (UV lamp 30W) followed directly by tangential filtration of methylene blue.

The feed reactor is pre-filled with the MB solution at a concentration of 25 mg / L, before adding the TiO₂ semiconductor of 1 g / L of the catalyst used in powder form. it is left stirring for 10 minutes, then the valve is opened which allows to send the reaction mixture before the photocatalytic degradation to the photochemical reactor to the microfiltration reactor, by means of a pump. the stirring speed is set, the recirculation flow rate of the reaction mixture depends on the applied pressure. samples are taken every 10 minutes. In BM photodegradation reactions, the pH of the suspension is about 6.5 the initial volume of the reaction mixture is 2L.

4 Results and discussion

4.1 Study of MB adsorption on TiO₂.

4.1.1 Time of equilibrium adsorption

Figure 7 shows that the increase in the initial BM concentration leads to a substantial increase in the amount of BM selected for the same amount of TiO₂. The amount of adsorbed BM becomes constant for an equilibrium time of 40 min and an initial concentration above C₀ = 60 ppm of BM.

Fig. 7. Effect of initial BM concentration on TiO₂ adsorption kinetics.

4.1.2 Influence of temperature on adsorption

In the range temperature considered, the temperature does not have a large effect on adsorption. A small increase in adsorbed amounts is observed with the increase in temperature (Fig.8).

Fig. 8. Effect of temperature on the adsorbed amount of BM on the photocatalyst.

Increasing the temperature would increase the mobility of ionized dye molecules, and would result in a widening of the pores in the internal structure of the adsorbent. This would allow dye molecules to penetrate.

4.1.3 Influence of pH

The curve in Figure 9 shows that the pH parameter improves the removal percentage, when the pH increases from 4 to 7 the percentage of elimination increases from 34 % to 91 % and when the pH changes from 7 to 14 a decrease from 91 % to 77 %. The maximum percentage

of elimination is 91 % which corresponds to the zero load point (ZLP) for TiO₂ particles at pH = 6.8.

Fig. 9. Effect of pH on BM equilibrium adsorption rate in darkness

4.1.4 Influence of TiO₂ concentration on adsorption rate

The results of the evolution of the adsorbed amount of dye over contact time are shown in Figure 10 and show that the increase in the concentration of catalysts (TiO₂) causes an increase in the adsorption rate.

Fig. 10. Evolution of the adsorbed amount of the dye as a function of the concentration of TiO₂ in the dark.

4.2 Study of BM removal by TiO₂ photocatalysis

4.2.1 Effect of initial concentration

Before any study, photolysis alone of methylene blue under solar irradiation was carried out in aqueous solution. It was found to be negligible, since only 2 % discolouration of the dye is observed in 90 min. Moreover, Figure 11 shows that, when irradiating the solution with a concentration of TiO₂ of 0,2 g/L, the dye is completely eliminated for low concentrations.

Fig. 11. Effect of initial concentration on BM removal.

Logically, the effectiveness of discolouration decreases with the increase of the dye concentration. Some justifications of this behaviour can be considered. First, it is possible that the photogeneration of h⁺ holes and/or OH[•] radicals on the catalyst surface may be reduced due to the covering of the active sites by the dye. Another justification would be that the absorption of a significant amount of UV by dye molecules rather than by the surface of TiO₂ reduces the intensity of the absorbed radiation at the catalyst, thus reducing the efficiency of the photocatalytic reaction.

4.2.2 Influence of pH on photocatalysis

Since the pH of the dye solution is an essential parameter for the progression of degradation, comparative experiments were carried out at different pH values: an acidic pH (3.3), two of the basic pH (11.4 ; 13.3) and a natural pH (7.7). Figure 12 illustrates the variation in the amount of dye removed as a function of the pH of the solution at a fixed temperature.

Fig. 12. Effect of pH on BM removal.

4.3 Study of BM removal on the microfiltration membrane

4.3.1 Test of permeability

Fig. 13 shows that the water flux through the membrane depends on the applied pressure but the stabilization of the flux needs about 0.5 hour due to formation of a polarization layer. The permeability was determined from the values of flux measured after stabilisation for each working pressure. The curve given the flux vs. pressure is a straight line with slope equal to about 121.6 L/h.m².bar which corresponds to the permeability of the membrane (Fig.14).

Fig. 13. Evolution of water permeation flux as a function of time.

Fig. 14. Evolution of water permeation flux as a function of pressure.

4.3.2 Filtration of BM on membrane ZrO₂/phosphate and ZrO₂/Clay

- Filtration on ZrO₂/phosphate: The results presented in Figure 15 show that the release rate reaches a maximum value of 3.5 % after 40 minutes of filtration. This confirms that the BM is not well retained by a microfiltration membrane.

Fig. 15. Filtration of BM without TiO₂ and without irradiation on ZrO₂/Phosphate

Next, we carried out a filtration in the presence of TiO₂ through the membrane of ZrO₂/Phosphate under the same conditions of BM concentration and pressure in the presence of TiO₂. Figure 16 showed that the rejection rate improved by comparing it with the previous figure. This can be explained by an adsorption of BM on TiO₂.

Fig. 16. Filtration of BM in the presence of TiO₂ and without irradiation on ZrO₂/Phosphate.

- Filtration on ZrO₂/clay : We carried out the same study but this time with microfiltration membrane based on clay.

Fig. 17. Filtration of BM without TiO₂ and without irradiation on ZrO₂/Clay.

After a filtration test on a microfiltration membrane, we found that the release rate (Figure 17) reaches a maximum value of 3.8 % after 40 min. This confirms that the BM is not well retained by a microfiltration membrane. The results presented in Figure 18 show that the release rate has improved compared to the absence of TiO₂ and irradiation and that fuel a value of 38 % after 40 minutes of filtration. This can be explained by an adsorption of BM on TiO₂.

Fig. 18. Filtration of BM in the presence of TiO₂ and without irradiation on ZrO₂/Clay.

4.4 Study of photodegradation and microfiltration membrane separation

The rejection rate of the ceramic membrane for the TiO₂ photocatalyst with two membranes was shown in Figure 19.

In the initial period of the microfiltration, the rejection rate for TiO₂ particles was more than 98%. After 40 min, the rejection rate completely TiO₂ particles was more than 99.5%. Meanwhile, no TiO₂ particles could be detected in the permeation liquid. This showed that TiO₂ photocatalyst was separated completely.

In order to measure the photocatalyst degradation rate in the coupling reactor, the photocatalytic oxidation of methylene blue was conducted in the coupling reactor. The result is shown in Figure 20. The degradation reaches 75% in 1 hours of filtration.

Fig. 19. The rejection rate of TiO₂.

Fig. 20. The rejection rate methylene blue solution

5 Conclusion

The preparation and characterization of a new microfiltration membrane based on Moroccan clay has been described and used in this work.

Different tests were studied to confirm the efficiency of the direct coupling of photodegradation and filtration and determine the rate of release of TiO₂ particles through the microfiltration membrane.

The photocatalysis membrane separation coupling reactor system was studied. The rejection rate of TiO₂ particles, the microfiltration flux and the photocatalytic degradation rate of methylene blue was investigated in the reactor under optimized operating conditions. This coupling reactor can meet the needs of both the separation of the particles and the photocatalytic reaction, and it is suitable for continuous and pilot scale operations.
