Abstract. This study involved conducting an experimental and numerical investigation on the effects of the air-to-fuel ratio (AFR), engine speed, and engine load on the inlet gas component of a three-way catalyst (TWC) and on the effects of noble metal loading, noble metal ratio, and carrier pore density on the emission conversion efficiency. The results showed that AFR can significantly affect the raw emissions of NO_x and THC, and better emission conversion efficiency of a TWC can be reached when AFR is controlled between 0.995 to 1. Compared with engine speed, engine load has a relatively small effect on exhaust temperature but greatly affects the flow velocity and NO_x and THC emissions. Increasing the content of Pt in the catalyst can improve the THC conversion efficiency. For low Pt and Pd-Rh catalysts, the THC conversion effect is significantly deteriorated. The content of Rh affects the NO_x conversion, and NO_x conversion efficiency at high speeds is significantly reduced when Rh content is reduced. Higher carrier pore density can slightly improve the catalytic reaction rate and emission conversion efficiency at high engine speeds. However, high conversion efficiency can be maintained even after aging.

1 Introduction

Due to stringent emissions regulations and the high cost of diesel fuel, alternative fuels provide solutions to an array of environmental and economic problems. Among alternative gaseous fuels, natural gas is regarded as the most promising for internal combustion engine [1-4]. Compared with gasoline, natural gas (NG) shows many advantages as motor fuel. A higher octane number leads to a lower tendency to knock and makes it easier to achieve a higher compression ratio and, therefore, better thermal efficiency. In terms of safety, natural gas is volatile, and it has a higher spontaneous combustion temperature and flammable limit. In addition, natural gas has a lower carbon content, and as motor fuel, its CO₂ emissions are lower compared with gasoline and diesel [5-6].

Lean-burn operation and stoichiometric operation are the two main routes of spark ignition (SI) in natural gas engines. Before the implementation of Euro-VI emission standards on heavy-duty engines, lean-burn mode was commonly applied to NG SI engines due to its lower knock tendency and better thermal efficiency [7,8]. In order to meet the stringent emissions requirements of non-methane total hydrocarbons (NMHC), CH₄ and nitrogen oxides (NO_x) in the latest emission standard, heavy-duty NG SI engines are designed to operate on a stoichiometric mixture combined with a three-way catalyst (TWC) and an ammonia slip catalyst (ASC). This mode is generally recognized as the most effective for NG engines due to its very low emissions and after-treatment costs compared with lean burn operation [9-11].

Currently, the TWC catalyst typically has a dual-layer washcoat applied to a cordierite substrate. In general, the underlayer is alumina rich, and the top layer contains oxygen storage (OSC) components, mainly Ce-Zr-mixed oxides. Both layers contain dispersed platinum group metal (PGM) components [12, 13]. Ce-Zr-mixed oxides, are added to the TWC formulation to buffer the perturbations near the stoichiometric operation of engines. Zirconium oxide itself have no OSC, but its incorporation with cerium oxides can improve the thermal stability and enhance the oxygen transport under lean/rich gas cycling reaction conditions [14]. At first, TWC formulation for natural gas engines was mainly referred to gasoline engines [15]. The active components were mainly platinum (Pt), a small amount of rhodium (Rh) and CeO₂ as a performance additive[16]. However, 90% to 95% of hydrocarbon emissions in the exhaust gas of natural gas engines are CH₄. CH₄ is difficult to oxidize catalytically, and the exhaust gas also contains a large amount of water vapor and a small amount of SO₂. Using gasoline formulation may reduce CH₄ conversion efficiency to less than 15% and cause poisoning and catalyst deactivation. Therefore, a TWC for gasoline vehicles is not suitable for the purification of natural gas engines [17,18]. Other than the catalyst and carrier, the catalytic performance of a TWC is also affected by operating conditions, such as the air-to-fuel ratio (AFR), engine speed, and engine load. The TWC efficient working window of natural gas engines is narrower than that of gasoline engines. When AFR is controlled toward the lean-burn side, the conversion efficiency of hydrocarbons and NO_x decreases rapidly [19]. Moreover, noble metal composition can influence the conversion efficiency of emissions, which is caused by complicated coherent effects or synergistic effects among different noble metals and additive.

Therefore, research on TWCs is particularly important for natural gas engines using stoichiometric operation. Some research on the performance of TWCs for natural gas engines has been conducted, but most studies carried out sample tests, so there are still few studies based on engine tests. Huo et al. [20] studied the effect of the noble metal ratio on the catalytic performance of natural gas engines on a sample test bench and found that a certain percentage of Pt had a promoting effect on CH₄ and NO_x conversion efficiency but basically no effect on CO conversion efficiency. Zhang et al. [21] used Pd and a small amount of Pt as components to conduct comparative analysis through a sample test. The results showed that Al₂O₃/SiO₂ as a coating material has good anti-sulfur poisoning ability and catalytic performance. Xi et al. [22] found that because of the reliance of NO_x conversion on CO and H₂, CH₄ conversion can strongly affect NO_x conversion. Hajbabaei et al. [4] found that the stoichiometric engine significantly reduced NO_x and THC emissions compared to the lean-burn engine but also resulted in higher levels of CO and ammonia (NH₃) emissions. Takayuki [23] and Oh [24] investigated the effect of noble metals in the catalyst on emissions, finding that Pd had the best effect on the conversion of CH₄, whereas Pt and Rh were less effective. The high-efficiency working window of Pd is narrow, and when AFR increases, the conversion efficiency of CH₄ decreases significantly. Some numerical study on TWC models have also been carried out. Maio et al. [25] investigate the effect of very fast composition transitions of the engine exhaust typical in real-world driving operating conditions. A

predictive model of catalyst behaviour with oxygen storage and release of a heavy-duty engine powered with NG was developed. Zeng et al. [26] establish a kinetic model of three-way catalyst and found that lower exhaust emission on a natural gas engine with a TWC can be achieved with an optimal dithering amplitude of AFR.

In order to determine the effect of the engine operation condition on the inlet state of a TWC and the effect of the TWC parameter on the conversion efficiency of main emissions, a bench test and numerical simulation were conducted in this study. This paper aims to reveal the effects of AFR, engine speed, and engine load on the inlet gas component of TWCs as well as the effects of noble metal loading, noble metal ratio and carrier pore density on the conversion efficiency of NOx and THC to provide TWC optimization guidelines for natural gas engines.

2 Experimental setup and simulation

2.1. Test platform and experimental apparatus

A six-cylinder, 12.42-liter turbocharged NG SI engine with a compression ratio of 11.46:1 was used for this experimental study. The specifications of the tested engine are shown in Table 1. A continuous-flow valve was employed for precise fuel supply control. The AFR was controlled by a closed-loop control system with a broadband oxygen sensor, and AFR was controlled by default at 0.995. The schematic of the experimental device is illustrated in Fig. 1.

Table 1. Specifications of tested engine.

Parameter	Value
Engine type	In-line six-cylinder
Displacement (L)	12.419
Bore (mm)	126
Stroke (mm)	166
Compression ratio	11.46:1
Intake mode	Turbocharged, intercooler
Fuel type	Natural gas
Mixture formation	Continuous flow valve system
Ignition mode	High energy spark ignition
Combustion chamber	Flat head, bowl piston
Maximum torque (N·m) / Speed (r/min)	2100 / 1300
Rated power (kW) / Speed (r/min)	330 / 1800

A high-pressure loop external exhaust gas re-circulation (EGR) system was implemented, which consisted of an EGR cooler, a one-way valve and a cold-side EGR valve. The EGR rate is defined by Eq. (1):

$$\text{EGR rate} = \frac{CO_{2-inlet}}{CO_{2-outlet}} * 100\%,$$

(1)

where $CO_{2-inlet}$ and $CO_{2-outlet}$ are the volumetric concentrations of carbon dioxide (CO2) in the intake and exhaust system, respectively.

The composition of natural gas has a significant impact on engine combustion. The natural gas used in the test had a high methane content, and the main properties of the fuel at 20°C and 1 standard atmosphere (atm) are shown in Table 2.

Table 2. The main compositions and properties of natural gas used in the test.

Compositions (vol%)		Property	
CH ₄	99.28	Higher heating value (MJ/kg)	55.34
C ₂ H ₆	0.42	Lower heating value (MJ/kg)	49.86
C ₃ H ₈	0.10	Molecular weight (g/mol)	16.17
iC ₄ H ₁₀	0.02	Density (kg/m ³)	0.6733
nC ₄ H ₁₀	0.02

Fig. 1. The schematic diagram of experimental setup and engine test bench.

To obtain the emission state of the engine, a SEMTECH-D emissions test system (Sensors, Inc., USA) was used to detect THC, NO_x, and CO concentration in the exhaust gas. The SEMTECH-FID module uses a heated flame ionization detector (HFID) to measure the total hydrocarbon concentration; its detection range is 0–3000 ppmc, and its resolution is 1 ppm. The SEMTECH-NO_x module directly measures NO and NO₂ concentration through non-dispersive ultraviolet (NDUV) to obtain the NO_x concentration value with a resolution of 0.3 ppm. Finally, the SEMTECH-FEM module uses non-dispersive infrared (NDIR) technology to measure the CO and CO₂ concentrations.

This study investigated the effect of operating conditions on TWC inlet parameters and the influence of TWC parameters on catalytic performance of natural gas engine exhaust. The test conditions were controlled by the test bench, and the electronic throttle, excess air ratio, and EGR rate were controlled using electronic control unit (ECU) software. Before each test, the engine was fully warmed and the backpressure of the engine was adjusted to 1.35 MPa with 100% load at 1800 r/min. An inlet air conditioning system was used to maintain the temperature, humidity, and pressure of the inlet air at 20 ± 2°C, 45 ± 3%, and 101 ± 1 kPa, respectively. During the test, the outlet cooling temperature of the intercooler was controlled by PID and the control target was set to 90°C.

To access the effects of AFR, engine speed, and engine load on the inlet state of TWCs, engine emission test operating points were designed as shown in Fig. 2. The engine was allowed to maintain a steady state for 2 minutes before emissions were sampled and data were collected.

To reduce the cost of TWCs, seven sets of TWCs with different parameters were designed and manufactured based on the mainstream TWC design parameters. The size of the TWC was 152.4 mm (length) × 304.8 (diameter). Additionally, all tested TWCs were tightly coupled with an ammonia slip catalyst (ASC); the size was 76.2 mm (length) × 304.8 mm (diameter), and it contained 10 g/ft³ Pt. The test intentions and specific design parameters of the seven sets of TWCs are shown in Table 3.

Fig. 2. The tested operating conditions.

Table 3. The parameters of tested three-way catalysts.

Case	Pore density (cpsi)	Noble metal loading (g/ft ³)	Noble metal ratio (Pt:Pd:Rh)
TWC1	400	150	45/100/15
TWC2	400	120	45/100/15
TWC3	400	100	45/100/15
TWC4	400	150	30/100/10
TWC5	400	150	55/85/10
TWC6	400	150	0/140/10
TWC7	600	150	45/100/15

2.2. Numerical simulation of three-way catalysts

In order to study the effect of engine control parameters and TWC parameters on catalytic conversion efficiency, a numerical model of the catalyst was established, including a catalytic reaction kinetics model, heat and mass transfer model, and control equations.

For the traditional TWC used on gasoline vehicles, Koltsakis [27] proposed a five-reaction mechanism based on the existing research. The exhaust components of natural gas engines are different from traditional gasoline engines, and also the catalyst is different. Therefore, the reaction mechanism of traditional TWCs is not applicable to natural gas engines. Considering that the main part of hydrocarbon emissions of natural gas engine is CH₄, the traditional five-reaction mechanism is adjusted, and the following reaction mechanism is established:

where QR is the heat of the chemical reaction, and its value is positive for endothermic reactions and negative for exothermic reactions.

The main component of the fuel used in the bench test was CH₄, which accounted for more than 99%,as shown in Table 2. To simplify the numerical model, only the oxidation and steam reforming reactions of CH₄ were considered, and other alkanes were ignored. Besides, the following assumptions were made: the gas flow state in each channel is consistent; there is neither heat nor mass transfer between the carriers; the geometric shape and the active components coated on the surface are the same; the inlet gas parameters (i.e., flow rate, temperature, composition) are consistent; the gas flow in is a fully developed laminar flow; the heat and mass transfer of the gas flow in the carrier channel in the axial direction is ignored; the inlet gas is an ideal gas with an average molecular weight, and there is no mutual reaction between the components.

For heat and mass exchange at the gas-solid boundary, the lumped parameter model was used, and the convective heat-transfer coefficient and convective mass-transfer coefficient were calculated using the dimensionless Nusselt number and the Sherwood number. In this paper, the Nusselt and Sherwood numbers were corrected by the bench test result and calculated by Eqs. (9) and (10):

$$Nu = 1.86(Re \cdot Pr \cdot \frac{d_h}{L_d})^{1/3} \tag{9}$$

$$Sh = 1.86(Re \cdot Sc \cdot \frac{d_h}{L_d})^{1/3} \tag{10}$$

According to the parameters of the carrier and the physical properties of the material, combined with the actual test environment conditions, the model parameters for numerical calculation were determined, as shown in Table 4.

Table 4. Parameters used in the numerical model.

Parameter	Value	Parameter	Value
ρ_g / kg/m ³	0.409	ρ_s / kg/m ³	2.5
λ_g / J/(m·s·K)	0.062	λ_s / J/(m·s·K)	2.0
C_{Pg} / J/(kg·K)	1.11×103	C_{Ps} / J/(kg·K)	1.0×103
T_∞ / K	300	v_g / m/s	10.3
Nu	3.66	ε	0.85
Ga / m ² /m ³	2900	D_h / mm	1.17

Based on the test results, the parameters of the oxidation reaction mechanism and the reduction reaction mechanism were calibrated separately to determine the activation energy and pre-finger factor of the reaction. The constructed chemical reaction mechanism is shown in Table 5, where the unit of the pre-factor is related to the reaction order, and the unit of activation energy of the chemical reaction is kJ/mol.

Table 5. Catalytic reaction mechanism used in simulation.

Chemical reaction	Pre-exponential factor	Activation energies (kJ/mol)
$\text{CO} + 1/2\text{O}_2 \Rightarrow \text{CO}_2$	1.69E+15	91450
$\text{CH}_4 + 2\text{O}_2 \Rightarrow \text{CO}_2 + 2\text{H}_2\text{O}$	5.12E+15	85600
$\text{H}_2 + 1/2\text{O}_2 \Rightarrow \text{H}_2\text{O}$	3.79E+12	21200
$\text{CO} + \text{NO} \Rightarrow \text{CO}_2 + 1/2\text{N}_2$	1.61E+15	52400
$\text{CH}_4 + \text{H}_2\text{O} \Rightarrow \text{CO} + 3\text{H}_2$	4.90E+12	128000

The conversion efficiency obtained by numerical simulation is in the form of a solid curve, and the bench test results are expressed in the form of scattered points, as shown in Fig. 3. It can be seen that the simulation results are basically consistent with the test results, and the deviation value is less than 2% in the common AFR range of the engine, which can meet the simulation needs.

Fig. 3. Comparison of simulation results and test results of catalytic conversion efficiency.

3 Results and discussion

3.1. Analysis of results under different operation conditions

3.1.1 Effect of air-to-fuel ratio

The inlet component of a TWC greatly affects the catalytic efficiency, and the inlet component of a TWC is determined by the engine operating conditions and control parameters. To analyse the effect of AFR on raw emissions of the engine and conversion efficiency of a TWC, steady-state tests were conducted at two operating conditions: 2100 N·m at 1300 r/min (full-load condition at maximum torque speed) and 1700 N·m at 1800 r/min (full-load condition at maximum power speed), which are the most important operating conditions for engine calibrations. EGR rate was controlled at 17.5%.

Fig. 4 and 5 show the effect of AFR on raw emissions of the engine and conversion efficiency of a TWC under the condition of 2100 N·m at 1300 r/min. As shown in Fig. 4(a), raw NOx emissions of the engine continuously increased with the increase of AFR from

0.975 to 1.02. Although the change of AFR slightly affected the combustion temperature and duration of high temperature, the increase of NO_x emissions was mainly caused by increasing oxygen concentration. The increase of AFR led to a significant drop in raw CO emissions but showed little effect on raw THC emissions. As can be seen in Fig. 4(b), the trends of raw NO_x, THC, and CO emissions at 1800 r/min were basically the same as those at 1300 r/min. NO_x emissions were relatively lower due to higher EGR rate and shorter high-temperature duration compared to that of 1300 r/min. THC and CO emissions increased when the engine speed increased from 1300 r/min to 1800 r/min. This was mainly due to the increase of unburnt fuel caused by wall and bulk quenching as well as leaking during valve overlapping [28].

Fig. 4. Raw emissions of the engine under the conditions of (a) 2100 N · m at 1300 r/min and (b) 1700 N · m at 1800 r/min.

As illustrated in Fig. 5(a), the conversion efficiencies of CO and THC were quite low when AFR < 0.99 due to the lack of O₂ in the exhaust gas. As NO_x emissions were lower and the reductant was sufficient due to higher CO and THC emissions, the conversion efficiency of NO_x was quite high, staying at more than 99%. As shown in Fig. 5(b), the conversion efficiency of CO was lower when AFR < 0.99, which was caused by lower NO_x emissions at 1800 r/min. When AFR increased from 0.99 to 1.00, the conversion efficiencies of CO and THC rapidly increased, and the efficiency of NO_x started to decrease. When AFR > 1.00, the conversion efficiency of CO stayed at about 100%, but the efficiency of THC decreased eventually, which was due to the oxidation activity of CH₄ being significantly reduced when AFR was controlled at the lean side.

Fig. 5. Conversion efficiency of emissions under the conditions of (a) 2100 N · m at 1300 r/min and (b) 1700 N · m at 1800 r/min.

3.1.2 Effect of engine speed

To clarify the effects of engine speed on the inlet gas state of TWCs, the EGR rate was kept constant at 17.5%, and the engine load was maintained at 75% load. Fig. 6 and Fig. 7 show the effects of engine speed on raw emissions, exhaust temperature, and flow velocity.

Fig. 6. Effect of engine speed on exhaust components.

As shown in Fig. 6, with the increase of engine speed, NOx emissions rapidly increased, reached a peak value near 1100 r/min and then started to decrease. The CO concentration showed little change with the increase of engine speed, whereas THC emissions decreased before eventually beginning to increase when the engine speed was more than 1100 r/min. As illustrated in Fig. 7, with the increase of engine speed, the exhaust temperature increased almost linearly from 510°C at 750 r/min to 590°C at 1800 r/min. However, the exhaust flow velocity through the catalyst carrier increased significantly, and the rate of increase slowed down slightly at high engine speeds.

Fig. 7. Effect of engine speed on exhaust temperature and flow velocity.

3.1.3 Effect of engine load

To evaluate the effects of engine load on the inlet gas state of TWCs, the EGR rate was kept constant at 17.5%, and the engine load was maintained at 1300 r/min. Figs. 8 and 9 illustrate the effects of engine load on raw emissions, exhaust temperature, and flow velocity. As shown in Fig. 8, the raw NOx concentration monotonously increased with the increase of engine load at 1300 r/min. Under low load conditions, the NOx concentration was low due to the low in-cylinder temperature. With the increase of engine load, NOx emissions

gradually increased until they became stable at high load. Similar to the trend in the test of engine speed, the CO concentration showed only slight changes with the change of engine load, staying at about 0.3%. THC emissions initially increased before eventually dropping down, and the maximum value was reached at about 30% load.

Fig. 8. Effect of engine load on exhaust components.

With the increase of engine load, the flow velocity increased almost linearly as shown in Fig. 9. The exhaust temperature varied greatly at high load and low load but remained basically unchanged at medium load.

Fig. 9. Effect of engine load on exhaust temperature and flow velocity.

3.2. Analysis of results of emissions using different three-way catalysts

3.2.1 Effect of noble metal loading

To access the effect of noble metal loading on the performance of TWCs, emission tests were conducted on the natural gas engine matching with three different TWCs. The noble metal loading was 150 g/ft³ for 1# TWC, 120 g/ft³ for 2# TWC and 100 g/ft³ for 3# TWC, as mentioned in Table 3.

Fig. 10 shows the effect of noble metal loading on the NOx conversion efficiency of TWCs at 75% engine load from 750 r/min to 1800 r/min. As the engine speed increased, the conversion efficiency of NOx started to decrease when the engine speed was higher than 1300 r/min. At high engine speeds, the higher flow velocity through the carrier led to the shorter residence time of exhaust gas in the catalyst, which reduced the NOx conversion

efficiency. Comparing three TWCs with different noble metal loading, it can be seen that 3# TWC showed relatively lower conversion efficiency at high engine speeds (about 1% lower). At low and medium engine speeds, noble metal loading seemed to have little effect on the conversion efficiency of NO_x.

Fig. 10. Effect of noble metal loading on NO_x conversion efficiency.

Fig. 11 illustrates the effect of noble metal loading on the THC conversion efficiency of TWCs at 75% engine load from 750 r/min to 1800 r/min. At low engine speeds, the THC conversion efficiencies of all three TWCs were high but eventually decreased with the increase of engine speed due to higher THC concentration and exhaust flow velocity. Overall, TWCs with noble metal loading of 150 g/ft³ and 120 g/ft³ showed little effect on THC conversion efficiency at all engine speed ranges, but TWCs with noble metal loading of 100 showed an obvious negative effect on THC conversion. A proper increase in noble metal loading can enhance the conversion efficiency of both NO_x and THC, but increasing the loading means increasing the cost of the after-treatment system, so it is necessary to comprehensively consider the catalytic performance and economy.

Fig. 11. Effect of noble metal loading on THC conversion efficiency.

3.2.2 Effect of noble metal ratio

To access the effect of noble metal ratio on the performance of TWCs, emission tests were conducted on the natural gas engine matching with four different TWCs. The noble metal ratio (Pt: Pd: Rh) was 45:100:15 for 1# TWC (baseline), 30:100:10 for 4# TWC (less Pt), 55:85:10 for 5# TWC (more Pt), and 0:140:10 for 6# TWC (Pd-Rh), as mentioned in Table 3.

Fig. 12 shows the effect of noble metal ratio on the NO_x conversion efficiency of TWCs at 75% engine load from 750 r/min to 1800 r/min. At high engine speeds, 5# TWC and 6# TWC showed obvious drops in NO_x conversion efficiency, and the NO_x conversion efficiency of 4# TWC also showed a certain degree of decline. This is because rhodium is mainly used for the catalytic reduction of NO_x [22], so the content of Rh can greatly affect the conversion of NO_x. 1# TWC had a higher Rh content and showed a better NO_x conversion effect, whereas 5# TWC and 6# TWC had lower Rh contents and hence poorer NO_x conversion efficiency at high engine speeds.

Fig. 13 illustrates the effect of noble metal ratio on the NO_x conversion efficiency of TWCs at 75% engine load from 750 r/min to 1800 r/min. Similar to NO_x conversion, noble metal ratio showed little effect on THC conversion at low engine speed as the conversion ratio remained at more than 98%. However, when engine speed was high, it can be seen from the curve that the Pt content in the catalyst had a significant effect on THC emissions. Low-Pt TWC (4#) and Pd-Rh TWC (6#) both had a low conversion efficiency of THC. The 6# catalyst had no Pt and the main part of catalyst was Pd, which is more sensitive to AFR due to the narrow efficient working window, and thus a more obvious drop of THC conversion can be observed at high engine load. In contrast, the high-Pt catalyst (5#) improved the catalytic conversion efficiency of THC in the high-speed section, maintaining a higher efficiency at all speeds.

Fig. 12. Effect of noble metals ratio on NO_x conversion efficiency.

Fig. 13. Effect of noble metals ratio on THC conversion efficiency.

3.2.3 Effect of pore density of carrier

To access the effect of carrier pore density on the performance of TWCs, emission tests were conducted on the natural gas engine matching with two different TWCs. The pore density of the carrier was 400 channels per square inch (cpsi) for 1#TWC and 600 cpsi for 7#TWC. A comparison of carrier parameters is displayed in Table 6.

Table 6. Comparison of carrier parameters of 1# and 7#TWC.

Parameters of carrier	Pore density of carrier	
	400 cpsi	600 cpsi
Pore area (mm ²)	1.36	0.92
Geometric surface area per unit volume (m ² /m ³)	2897	3575
Porosity (%)	84.6%	85.9%
Pore wall thickness (mm)	0.102	0.076
Hydraulic diameter (mm)	1.17	0.96

Compared with the 400 cpsi carrier, the 600 cpsi carrier had a higher geometric surface area and porosity but a lower pore wall thickness and hydraulic diameter. The increase of the geometric surface area of the carrier can increase the contact area between the reaction gas and catalyst, thus enhancing the catalytic reaction rate. The smaller the hydraulic diameter, the higher the convective mass transfer coefficient, which promotes the heterogeneous catalytic reaction to some extent. To study the effect of carrier pore density on the catalytic reaction in the carrier, a TWC numerical model was established using the simulation method mentioned in Section 2.3. Based on the model, the catalyst reaction rate and gas temperature of two TWCs with different pore densities were simulated. After long-term use of the catalyst, the catalyst will age, and catalytic performance will be reduced. In order to simulate aging, catalyst relative activity α was introduced to characterize the degree of catalyst deactivation. The definition of relative activity is shown in Eq. (11) [29], and α was taken as 0.1 in simulation.

$$\alpha = \frac{\gamma_A}{\gamma_0}$$

(11)

where γ_A is the actual reaction rate of reactant A on catalyst and γ_0 is the reaction rate of reactant A on fresh catalyst.

Fig. 14 shows the change of the molar concentration of O₂ along the axial position of the carrier before and after aging. As shown in the figure, the catalytic oxidation rate in the TWC with 600 cpsi was faster, as the molar concentration of O₂ decreased by about 99% at 0.05 m, whereas in the TWC with 400 cpsi the molar concentration of O₂ decreased by about 99% at 0.069 m. Compared with the fresh catalysts, the rate of decrease of O₂ concentration was significantly slower in the aged catalysts. At the end of the simulation, both aged catalysts still contained much O₂, although the concentration of the 600 cpsi TWC was lower.

Fig. 14. Effect of pore density on oxidation reaction rate.

Fig. 15 shows the change of gas temperature along the axial position of the carrier before and after aging. Due to the larger geometric surface area of the carrier, the contact area between the reaction gas and catalyst increased in 7#TWC and led to a higher catalytic reaction rate. Thus, the catalytic reaction was more concentrated on the front side of the carrier and caused a rapid increase of gas temperature in the front of the carrier. As can be seen in the figure, the gas temperature increase rate in 7#TWC was much higher than that in 1#TWC, and the increase of gas temperature within a certain range helped the catalytic reaction proceed. Compared with fresh catalysts, the increase rates in the front of the carrier were much lower after aging. The middle and rear part of the carrier still contained much O₂; thus, the temperature tended to increase monotonically.

Fig. 15. Effect of pore density on gas temperature distribution.

Fig. 16 and Fig. 17 illustrate the effect of pore density on the NO_x and THC conversion efficiency of TWCs at 75% engine load from 750 r/min to 1800 r/min. As shown in Fig. 16, TWC with higher pore density showed little effect on NO_x conversion efficiency at low and medium speed conditions, and a slightly increased effect at high engine speeds. Similar to NO_x, the THC conversion efficiency of the 600 cpsi TWC was much higher than that of the 400 cpsi TWC, and its efficiency was increased by 0.68% at 1800 r/min. Overall, the increase of the pore density of the carrier can improve the catalytic performance of TWCs, especially at high engine speeds. In addition, the conversion efficiency of catalysts with higher pore density after aging was much higher than that of catalysts with low pore density. Increasing pore density also increases the cost of the after-treatment system, and the improvement of

catalytic performance is quite limited at low and medium speeds, and thus should be further discussed in engineering application.

Fig. 16. Effect of pore density on NOx conversion efficiency.

Fig. 17. Effect of pore density on THC conversion efficiency.

4 Conclusions

In order to study the effect of TWC parameters on the after-treatment performance of natural gas engines, bench tests and numerical simulations were conducted in this study. The effects of AFR, engine speed, and engine load on the inlet gas component of TWC, and the effects of noble metal loading, noble metal ratio, and carrier pore density on the conversion efficiency of NOx and THC were discussed. The main conclusions from the study are summarized as follows:

- (1) AFR can significantly affect the raw emissions of NOx and THC, and better emission conversion efficiency of TWC can be reached when AFR is controlled between 0.995 to 1. Increasing engine speed leads to higher NOx emissions, exhaust temperature and flow velocity. Compared with engine speed, engine load has a relatively small effect on exhaust temperature but greatly affects the flow velocity as well as NOx and THC emissions.
- (2) Increasing noble metal loading can improve the catalytic performance, especially at high engine speeds. Increasing the content of Pt in the catalyst can improve the THC conversion efficiency. For low Pt and Pd-Rh catalysts, the THC conversion effect is significantly deteriorated. The content of Rh affects the NOx conversion. When Rh

content is reduced, the catalytic conversion efficiency of NO_x at high speeds is significantly reduced.

- (3) Higher pore density of the carrier enhances the catalytic reaction rate and gas temperature in the carrier. Conversion efficiency is also improved at high engine speeds. After aging, TWC with high carrier pore density can still maintain high catalytic conversion efficiency.
