Abstract. In this study, a natural extract of Jerusalem artichoke was studied. The physicochemical properties of the concentrate obtained from the Jerusalem artichoke plant were studied. In mathematical modeling, there are methods of experimental statistical modeling. In this case, the results of experiments obtained on this installation are used to create a mathematical model of the technological process. The flow motion was studied for solution analysis. The importance of studying flow motion lies in determining the parameters that need to be taken into account in the simulation.

1 Introduction

Due to the high growth of food industry and pharmaceutical production, many artificial extracts have been synthesized and these extracts are widely used in food products. Compared to natural extracts, their biological activity, taste and vitamins are insufficient. Many natural food extracts contain biologically active substances, vitamins, amino acids, carbohydrates, aromatic substances and mineral salts. Pigments are composed of anthocyanins, carotenoids, chlorophyll and xanthophylls. Natural extracts are obtained mainly from plant raw materials, secondary raw materials from vegetables and fruits. Natural solutions are mainly obtained by extraction methods. Ethyl alcohol solution, water, vegetable oil, etc. are used as extractants.

One popular source of inulin is the tuber of topinambur (Fig. 1.), which belongs to the Asteraceae family of the Sunflower family and is 2 to 4 m high and weighs up to 300 g. Nowadays, it is believed that this vegetable is native to North America, where it grows in large quantities under natural conditions. Its development cycle is similar to that of potatoes.
Fig. 1. Topinambour tubers

Topinambour has a very low degree of heavy metal accumulation [5] and contains a large amount of dry matter (18-20 %), it also contains a wide range of minerals, such as (mg % per dry matter): 10.1 iron, 44 manganese, 78.8 calcium, 31.7 magnesium, 1382.5 potassium and 17.2 sodium [7]. Topinambur dynamically accumulates silicon from the soil, amounting to up to 8% in relation to the dry matter.

Topinambour processing technology for the production of inulin.

There are over 2,000 types of products containing inulin and oligofructose worldwide. In particular, in the Russian Federation the common inulin-containing products are: desugared “Russian chocolate”, baby food “Heinz”, coffee “For slimming” by “LeovitNutrio”, kefir “Biomax effective” by “Wimm-BillDann”, drinking yogurts “Ermigurt prebiotic” by “Ermann”, etc. There are only three major inulin producers on the world market: Beneo-Orafti from Belgium has 70% of the market, while Cosucra, also from Belgium, and Sensus from Holland have a roughly equal share [3]. Inulin is predominantly produced in the industry from chicory, which is easier to process due to the regular shape of the root, although its content in topinambur is about the same. The molecular chain of inulin from chicory is longer [8], which is essential for the technological performance of the polysaccharide, for example for fat imitation. The solubility of inulin in water depends on the chain length, which decreases with increasing chain length, with improved gel-forming properties, and increased resistance to hydrolysis. In China, inulin is grown and produced from topinambour with a high maltodextrin content - up to 50%. In the Russian Federation, inulin production, particularly from topinambour, is only beginning to develop for the production of dietary supplements, with dried crushed topinambour or its juice being mainly used.

Promising ways of obtaining extracts from plant raw materials and their drying.

In food processing, the main traditional dissolution and leaching methods include closed batch, continuous direct and counterflow, and filtration-flow or percolation processes with a fixed bed [9]. In closed batch processes mechanical or pneumatic agitation is used to intensify the process, in which gas is used not only for agitation but also as an oxidizer. In the case of intensive mixing the disperse particles move with a vector of velocity that changes its direction, and with a numerical value that is lower or higher than that of the washing stream. This is determined by the inertia of the dispersed particles and leads to the possibility of intensification of dissolution and leaching, despite the reduction of the driving force of the processes in striving towards the equilibrium state [10]. In the case of low-intensity mixing, the dispersed particles hover in the fluid while in suspension, moving successively in the upward and downward flows of the fluid phase washing over them at a...
certain rate determined by gravitational and inertial forces, the latter being superior to the former in the inertial regime \[11, 12\]. These non-stationary processes are simple to implement but inefficient because of the well-known disadvantages of periodic processes.

More common in industry are continuous dissolution and extraction processes. These processes may also be carried out in stirrers with continuous injection and withdrawal of contacting phases into the apparatus. In this method, the intensity is low, due to the contact between solid product and solution with a concentration that, due to agitation, approaches the concentration at saturation, which reduces the driving force and speed of the processes, relative to the average speed of a single batch operation, in which the equilibrium concentration is only reached when it is completed. In addition, it is possible for individual dispersed particles to "overshoot" in a single apparatus \[12\]. At the same time their residence time in the apparatus may not be sufficient to obtain a high degree of extraction of the extracted components.

Therefore, for a more significant intensification of the extraction process, the extraction process is conducted in cascade units, where the hydro module is moved by gravity flow through series-connected apparatuses with agitators. In this organization of the process, the driving force is permanently reduced from one stage to another (the number of stages usually does not exceed 6) and, unlike the process in a single apparatus, when fresh solvent and the final concentrated solution come into contact, a relatively high degree of extraction can be achieved \[12\]. The effect can be strengthened by organizing countercurrent processes, where in the countercurrent flow of solids and liquid in the battery apparatus the fresh solvent at the end of the unit is in contact with the leached material, and at the beginning the feed material interacts with the concentrated solution, which makes the unit operation more uniform \[7\]. With this arrangement of the process flow, fresh solvent is introduced at the end of the unit, which makes it possible to increase the degree of extraction of components from the pores of the solid product, and on the other side of the unit to use the solution for surface extraction more efficiently.

2 Methods

The limiting factor for the extraction rate is the internal mass transfer in the solid phase, which it is advisable to model in order to calculate the concentration distribution in the volume of the starting product during extraction, which determines its duration and compliance with technological limits to ensure the quality of the finished product.

The task of mass transfer modelling is to determine the duration of phase contact determined by extraction kinetics.

Mass transfer is effected by the difference in content of the transferred component on the surface and inside the original product—crushed topinambour, which consists of particles whose shape is close to cylindrical, so the equivalent diameter calculated from the volume of the particle is taken as the characteristic size.

In order to find the unsteady concentration fields, a system of differential equations for heat and mass transfer must be solved. The mass transfer equation for the one-dimensional problem is as follows:

\[
\frac{\partial c}{\partial \tau} = \bar{D} \frac{\partial^2 c}{\partial x^2}
\]

where \(c\) is the concentration of the transferred component in the feed or raffinate, \(x\) is the particle depth coordinate, \(\tau\) is the current process time, \(\bar{D}\) is the average molecular diffusion coefficient in the solid phase.
surface of a cylindrical particle of small diameter 

\[ d_{ekv} = 4 \text{ mm internal and externa} \]

mass transfer. Hence, as the first coordinate \( x \) characterizing the particle and on which the desired function \( c(x, \tau) \) depends \( c(x, \tau) \), one can take its radius \( r \), mm, that is \( x = 0 \ldots r_{ekv} \).

\[ X_n = \text{rekv} \]

The initial value of the \( x \)-coordinate corresponding to the surface of the particle:

\[ X_n = 0 \]

The final value of the \( x \)-coordinate corresponding to the center of the particle:

\[ X_k = r_{ekv} \]

In this simulation option it is not necessary to carry out the calculation in polar coordinates, since the concentration change \( s \) in uniform surface mass transfer are not determined by its direction. As another coordinate in the finite difference grid, when used to solve the mass transfer equation, we take the duration of the extraction process \( \tau \), с.

\[ \tau = 0 \ldots \tau_{ekv} \]

\[ \tau = 0. \]

\[ \tau = \tau_{ekv} \]

\[ \delta = \]...

\[ -D \frac{dy}{dx} \approx D \frac{(y_{elem} - y_p)}{\delta} = \beta_x (x_p - x_e) \]

\[ \beta_x \]

\[ x \]

\[ y_{elem} \]

\[ y_p \]

\[ x_e \]

\[ \delta \]

\[ D \]

\[ \beta_x \]...

\[ (BiT < 1, BiM < 1) \]

\[ \beta_x \]...

\[ (BiT < 1, BiM < 1) \]

\[ \beta_x \]...

\[ (BiT < 1, BiM < 1) \]
polar coordinates as temperature changes at uniform surface energy input are not determined by its direction [4]. Often desorption shrinkage is neglected to simplify models of the dewatering process [3, 6], which is excluded when drying dispersed high-moisture particles where significant shrinkage is observed. When using numerical methods for solving the heat transfer equation, it is possible to take into account the change of particle size in steps with a given step, which is provided by finite difference method applied in this work, where differentials are replaced by finite differences. Due to the fact that the exact change of the particle size in time cannot be studied experimentally practically, in realisation of the model it is assumed to change linearly from the initial to the final equivalent diameter determined empirically by disperse composition analysis [4, 6]. In the case under consideration, the finite temperature distribution along the particle radius of the previous zone will be the initial for the subsequent one. As another coordinate of the difference grid, instead of dewatering time, the associated current humidity of the treatment determined in previous studies is used, whose change depending on the duration of the process is also divided into characteristic zones. By sequentially combining the temperature fields of the individual zones, a common temperature field is obtained.

3 Results and discussion

Using a mathematical numerical finite difference method, the concentration and temperature fields for the extraction of inulin from topinambour and convective drying of the inulin solution in a spray state were obtained.

In the one-dimensional formulation of the problem, in its most general form, the energy transfer equation for volumetric energy input is as follows:

\[ c_p(x, T, w) \frac{\partial T}{\partial \tau} - \frac{\partial}{\partial x} \left( \lambda(w, x, T) \frac{\partial T}{\partial x} \right) + \varepsilon \cdot r(w, x, T) \cdot \rho(w, x, T) \cdot \frac{\partial w}{\partial \tau} + W(w, x, T) = 0 \]

Here \( r \) is the amount of energy for the vapour formation of 1 kg of moisture when the entropic component is taken into account:

\[ r = 3118.4581 \cdot 10^3 - 2286.66 \cdot T - 55.5 \cdot RT \cdot \ln A_w + 55 \cdot 0.5 \cdot T \frac{\partial \Delta S}{\partial U} \]

Knowing \( \frac{\partial w}{\partial \tau} = f(w) \) and \( w = f(\tau) \) and omitting the sign of the mean and the arguments of the functions, we obtain

\[ \frac{\partial T}{\partial w} = \frac{a}{\partial w/\partial \tau} \frac{\partial^2 c}{\partial x^2} + \frac{r(w, T)\rho(w, T)}{\rho(w, T)} \frac{\partial \rho}{\partial \tau} \]

\[ \frac{\partial \tau}{\partial w} = a \frac{\partial^2 c}{\partial x^2} + \frac{r}{\varepsilon} \]

CONMECHYDRO - 2023
The initial conditions are given with respect to the uniform temperature distribution at $W_H, T = T_0$:

$W_{H} = W_{H_{0}}$, $T = T_{0}$

$T(x, w_{H}) = T_{0}$

Since between surfaces of neighbouring particles with the same temperature there is a mutual reflection of thermal energy, the radiant heat transfer between the particles can be neglected with sufficient accuracy.

Solving equation (6) under the above boundary conditions, we obtain the functional dependence $t = f(w, x)$.

Then, by substituting $w = f(\tau, W_H, T)$ we define the function $t = f(x, \tau, W_H, T)$.

To increase both arguments in the drying process we will carry out the replacement of moisture $w$ to dry matter content $c$.

Fig. 2 shows a graphical interpretation of the concentration fields during inulin extraction.

Considering the calculated temperature fields (Fig. 3), it can be concluded that insignificant temperature gradients exist, which result in uniform volumetric heating and 'gentle' moisture removal, as the material temperature during drying did not exceed $T = 328$ K.
Fig. 3. Temperature field at $W_n = 0.95$ kg/kg; $T = 383$ K; $c$, $x$ are the order numbers of the steps ($\Delta c$, $\Delta x$).

Periodic temperature peaks, corresponding to jumps in the drying rate curves, are observed. In sections with approximately constant temperature the removal of free moisture occurs [8, 5]. An increase in temperature is caused by the expansion of structural moisture confined in closed cells and capillaries, blocked by liquid meniscuses, which leads to the so-called "greenhouse" effect and a decrease in the rate of moisture removal.

4 Conclusions

The adequacy of the developed mathematical model of the drying process was evaluated by the final temperature in the powder layer of dried inulin extract particles (particle surface temperature). Based on a comparison of the test multimeter readings with simulation results, it was shown that the average temperature of the powder leaving the dryer at three repetitions was 322 K, which ensures that the quality is maintained during drying. The relative error of the model temperature in relation to the experimentally determined temperature of the powder at the outlet of the dryer did not exceed 6%, which indicates the adequacy of the developed model and the possibility of its implementation in industry.
